

RDDs and key-value pairs

RDDs of key-value pairs

- Spark supports also RDDs of key-value pairs
 - Key-value pairs in python are represented by means of python tuples
 - The first value is the key part of the pair
 - The second value is the value part of the pair
- RDDs of key-value pairs are sometimes called “pair RDDs”

RDDs of key-value pairs

- RDDs of key-value pairs are characterized by specific operations
 - `reduceByKey()`, `join()`, etc.
 - These operations analyze the content of one group (key) at a time
- RDDs of key-value pairs are characterized also by the operations available for the “standard” RDDs
 - `filter()`, `map()`, `reduce()`, etc.

RDDs of key-value pairs

- Many applications are based on RDDs of key-value pairs
- The operations available for RDDs of key-value pairs allow
 - “grouping” data by key
 - performing computation by key (i.e., by group)
- The basic idea is similar to the one of the MapReduce-based programs in Hadoop
 - But there are more operations already available

Creating RDDs of key-value pairs

Creating RDDs of key-value pairs

- RDDs of key-value pairs can be built
 - From other RDDs by applying the `map()` or the `flatMap()` transformation on other RDDs
 - From a Python in-memory collection of tuple (key-value pairs) by using the `parallelize()` method of the `SparkContext` class

Creating Pair RDDs

- Key-value pairs are represented as tuples composed of two elements
 - Key
 - Value
- The standard built-in Python tuples are used

**RDDs of key-value pairs by
using the Map transformation**

RDDs of key-value pairs by using the map transformation

- Goal
 - Define an RDD of key-value pairs by using the map transformation
 - Apply a function **f** on each element of the input RDD that **returns one tuple for each input element**
 - The new RDD of key-value pairs contains one tuple **y** for each element **x** of the “input” RDD

RDDs of key-value pairs by using the map transformation

- Method
 - The standard `map(f)` transformation is used
 - The new RDD of key-value pairs contains **one tuple `y`** for **each input element `x`** of the “input” RDD
 - $y = f(x)$

RDDs of key-value pairs by using the map transformation: Example

- Create an RDD from a textual file containing the first names of a list of users
 - Each line of the file contains one first name
- Create an RDD of key-value pairs containing a list of pairs (first name, 1)

RDDs of key-value pairs by using the map transformation: Example

```
# Read the content of the input textual file  
namesRDD = sc.textFile("first_names.txt")
```

```
# Create an RDD of key-value pairs  
nameOnePairRDD = namesRDD.map(lambda name: (name, 1))
```

RDDs of key-value pairs by using the map transformation: Example

```
# Read the content of the input textual file  
namesRDD = sc.textFile("first_names.txt")
```

```
# Create an RDD of key-value pairs
```

```
nameOnePairRDD = namesRDD.map(lambda name: (name, 1))
```

nameOnePairRDD contains key-value pairs (i.e., tuples) of type (string, integer)

**RDDs of key-value pairs by using
the flatMap transformation**

RDDs of key-value pairs by using the flatMap transformation

- Goal
 - Define an RDD of key-value pairs by using the flatMap transformation
 - Apply a function **f** on each element of the input RDD that **returns a list of tuples for each input element**
 - The new PairRDD contains all the pairs obtained by applying **f** on each element **x** of the “input” RDD

RDDs of key-value pairs by using the flatMap transformation

- Method
 - The standard `flatMap(f)` transformation is used
 - The new RDD of key-value pairs contains the tuples returned by the execution of `f` on each element `x` of the “input” RDD
 - `[y] = f(x)`
 - Given a element `x` of the input RDD, `f` applied on `x` returns a list of pairs `[y]`
 - The new RDD is a “list” of pairs contains all the pairs of the returned list of pairs. It is not an RDD of lists.
 - `[y]` can be the empty list

RDDs of key-value pairs by using the flatMap transformation: Example

- Create an RDD from a textual file
 - Each line of the file contains a set of words
- Create a PairRDD containing a list of pairs (word, 1)
 - One pair for each word occurring in the input document (with repetitions)

RDDs of key-value pairs by using the flatMap transformation: Example v1

```
# Define the function associated with the flatMap transformation
def wordsOnes(line):
    pairs = []
    for word in line.split(' '):
        pairs.append( (word, 1) )
    return pairs

# Read the content of the input textual file
linesRDD = sc.textFile("document.txt")

# Create an RDD of key-value pairs based on the input document
# One pair (word,1) for each input word
wordOnePairRDD = linesRDD.flatMap(wordsOnes)
```

RDDs of key-value pairs by using the flatMap transformation: Example v2

```
# Read the content of the input textual file
linesRDD = sc.textFile("document.txt")

# Create an RDD of key-value pairs based on the input document
# One pair (word,1) for each input word
wordOnePairRDD = linesRDD.flatMap(lambda line: \
                                   map(lambda w: (w, 1), line.split('')))
```

RDDs of key-value pairs by using the flatMap transformation: Example v2

```
# Read the content of the input textual file  
linesRDD = sc.textFile("document.txt")
```

```
# Create an RDD of key-value pairs based on the input document  
# One pair (word,1) for each input word
```

```
wordOnePairRDD = linesRDD.flatMap(lambda line: \
```

```
map(lambda w: (w, 1), line.split(' ')))
```

This is the map of python.
It is not the Spark's map transformation.

**RDDs of key-value pairs by
using parallelize**

RDDs of key-value pairs by using parallelize

- Goal
 - Use the parallelize method to create an RDD of key-value pairs from a local python in-memory collection of tuples
- Method
 - It is based on the standard `parallelize(c)` method of the `SparkContext` class
 - Each element (tuple) of the local python collection becomes a key-value pair of the returned RDD

RDDs of key-value pairs by using parallelize: Example

- Create an RDD from a local python list containing the following key-value pairs
 - ("Paolo", 40)
 - ("Giorgio", 22)
 - ("Paolo", 35)

RDDs of key-value pairs by using parallelize: Example

```
# Create the local python list  
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]  
  
# Create the RDD of pairs from the local collection  
nameAgePairRDD = sc.parallelize(nameAge)
```

RDDs of key-value pairs by using parallelize: Example

Create the local python list

```
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]
```

Create a local in-memory python list of key-value pairs (tuples). This list is stored in the main memory of the Driver.

RDDs of key-value pairs by using parallelize: Example

```
# Create the local python list  
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]
```

```
# Create the RDD of pairs from the local collection  
nameAgePairRDD = sc.parallelize(nameAge)
```

Create an RDD of key-value pairs based on the content of the local in-memory python list.
The RDD is stored in the “distributed” main memory of the cluster servers

Transformations on RDDs of key-value pairs

Transformations on RDDs of key-value pairs

- All the “standard” transformations can be applied
 - Where the specified “functions” operate on tuples
- Specific transformations are available
 - E.g., `reduceByKey()`, `groupByKey()`, `mapValues()`, `join()`, ...

ReduceByKey transformation

ReduceByKey transformation

- Goal
 - Create a new RDD of key-value pairs where there is **one pair for each distinct key k** of the input RDD of key-value pairs
 - The value associated with key k in the new RDD of key-value pairs is computed by applying a function f on the values associated with k in the input RDD of key-value pairs
 - The function f must be **associative** and **commutative**
 - otherwise the result depends on how data are partitioned and analyzed
 - The data type of the new RDD of key-value pairs is the same of the “input” RDD of key-value pairs

ReduceByKey transformation

- Method
 - The reduceByKey transformation is based on the `reduceByKey(f)` method of the `RDD` class
 - A function `f` is passed to the reduceByKey method
 - Given the values of two input pairs, `f` is used to combine them in one single value
 - `f` is recursively invoked over the values of the pairs associated with one key at a time until the input values associated with one key are “reduced” to one single value
 - The returned RDD contains a number of key-value pairs equal to the number of distinct keys in the input key-value pair RDD

ReduceByKey transformation

- Similarly to the `reduce()` action, the `reduceByKey()` transformation aggregate values
- However,
 - `reduceByKey()` is executed on RDDs of key-value pairs and **returns a set of key-value pairs**
 - `reduce()` is executed on an RDD and **returns one single value** (stored in a **local python variable**)
- And
 - **`reduceByKey()` is a transformation**
 - `reduceByKey()` is executed lazily and its result is stored in another RDD
 - Whereas `reduce()` is an action

ReduceByKey transformation

- Shuffle
 - A **shuffle** operation is executed for computing the result of the **reduceByKey()** transformation
 - The result/value for each group/key is computed from data stored in different input partitions

ReduceByKey transformation: Example

- Create an RDD from a local python list containing the pairs
 - ("Paolo", 40)
 - ("Giorgio", 22)
 - ("Paolo", 35)
 - The key is the first name of a user and the value is his/her age
- Create a new RDD of key-value pairs containing one pair for each name. In the returned RDD, associate each name with the age of the youngest user with that name

ReduceByKey transformation: Example

```
# Create the local python list
```

```
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]
```

```
# Create the RDD of pairs from the local collection
```

```
nameAgePairRDD = sc.parallelize(nameAge)
```

```
# Select for each name the lowest age value
```

```
youngestPairRDD = nameAgePairRDD.reduceByKey(lambda age1, age2:\n                                              min(age1, age2))
```

ReduceByKey transformation: Example

```
# Create the local python list  
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]
```

```
# Create the RDD of pairs from the local collection  
nameAgePairRDD = sc.parallelize(nameAge)
```

```
# Select for each name the lowest age value
```

```
youngestPairRDD = nameAgePairRDD.reduceByKey(lambda age1, age2:\n                                              min(age1, age2))
```

The returned RDD of key-value pairs contains one pair for each distinct input key (i.e., for each distinct name in this example)

FoldByKey transformation

FoldByKey transformation

- Goal
 - The foldByKey() has the same goal of the reduceByKey() transformation
 - However, foldByKey()
 - Is characterized also by a “zero” value
 - Functions **must be associative** but are not required to be commutative

FoldByKey transformation

- Method
 - The foldByKey transformation is based on the `foldByKey(zeroValue, op)` method of the `RDD` class
 - A function `op` is passed to the fold method
 - Given values of two input pairs, `op` is used to combine them in one single value
 - `op` is also used to combine input values with the “zero” value
 - `op` is recursively invoked over the values of the pairs associated with one key at a time until the input values are “reduced” to one single value
 - The “zero” value is the neutral value for the used function `op`
 - i.e., “zero” combined with any value `v` by using `op` is equal to `v`

FoldByKey transformation

- Shuffle
 - A **shuffle** operation is executed for computing the result of the **foldByKey()** transformation
 - The result/value for each group/key is computed from data stored in different input partitions

FoldByKey transformation: Example

- Create an RDD from a local python list containing the pairs
 - ("Paolo", "Message1")
 - ("Giorgio", "Message2")
 - ("Paolo", "Message3")
 - The key is the first name of a user and the value is a message published by him/her
- Create a new RDD of key-value pairs containing one pair for each name. In the returned RDD, associate each name the concatenation of its messages (preserving the order of the messages in the input RDD)

FoldByKey transformation: Example

```
# Create the local python list
nameMess = [("Paolo", "Message1"), ("Giorgio", "Message2"), \
            ("Paolo", "Message3")]

# Create the RDD of pairs from the local collection
nameMessPairRDD = sc.parallelize(nameMess)

# Concatenate the messages of each user
concatPairRDD = nameMessPairRDD.foldByKey("", lambda m1, m2:\
                                         m1+m2)
```

CombineByKey transformation

CombineByKey transformation

- Goal
 - Create a new RDD of key-value pairs where there is one pair for each distinct key **k** of the input RDD of key-value pairs
 - The value associated with the key **k** in the new RDD of key-value pairs is computed by applying user-provided functions on the values associated with **k** in the input RDD of key-value pairs
 - The user-provided “function” must be **associative**
 - otherwise the result depends how data are partitioned and analyzed
 - The **data type** of the new RDD of key-value pairs can be **different** with respect to the data type of the “input” RDD of key-value pairs

CombineByKey transformation

- Method
 - The combineByKey transformation is based on the `combineByKey(createCombiner, mergeValue, mergeCombiner)` method of the `RDD` class
 - The values of the input RDD of pairs are of type `V`
 - The values of the returned RDD of pairs are of type `U`
 - The type of the keys is `K` for both RDDs of pairs

CombineByKey transformation

- The **createCombiner** function contains the code that is used to transform a single value (type V) of the input RDD of key-value pairs into a value of the data type (type U) of the output RDD of key-value pairs
 - It is used to transform the first value of each key in each partition to a value of type U

CombineByKey transformation

- The **mergeValue** function contains the code that is used to combine one value of type U with one value of type V
 - It is used in each partition to combine the initial values (type V) of each key with the intermediate ones (type U) of each key

CombineByKey transformation

- The **mergeCombiner** function contains the code that is used to combine two values of type U
 - It is used to combine intermediate values of each key returned by the analysis of different partitions

CombineByKey transformation

- **combineByKey** is more general than `reduceByKey` and `foldByKey` because the **data types of the values of the input and the returned RDD** of pairs **can be different**
 - For this reason, more functions must be implemented in this case

CombineByKey transformation

- Shuffle
 - A **shuffle** operation is executed for computing the result of the **combineByKey()** transformation
 - The result/value for each group/key is computed from data stored in different input partitions

CombineByKey transformation: Example

- Create an RDD from a local python list containing the pairs
 - ("Paolo", 40)
 - ("Giorgio", 22)
 - ("Paolo", 35)
 - The key is the first name of a user and the value is his/her age
- Store the results in an output HDFS folder. The output contains one line for each name followed by the average age of the users with that name

CombineByKey transformation: Example

```
# Create the local python list
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]

# Create the RDD of pairs from the local collection
nameAgePairRDD = sc.parallelize(nameAge)

# Compute the sum of ages and
# the number of input pairs for each name (key)
sumNumPerNamePairRDD=nameAgePairRDD.combineByKey(\
    lambda inputElem: (inputElem, 1), \
    lambda intermediateElem, inputElem: \
        (intermediateElem[0]+inputElem, intermediateElem[1]+1), \
    lambda intermediateElem1, intermediateElem2: \
        (intermediateElem1[0]+intermediateElem2[0], \
         intermediateElem1[1]+intermediateElem2[1])
)
```

CombineByKey transformation: Example

```
# Create the local python list
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]
```

Given an input value (an age), it returns a tuple containing (age, 1)

```
# Compute the sum of ages and
# the number of input pairs for each name (key)
sumNumPerNamePairRDD=nameAgePairRDD.combineByKey(\
    lambda inputElem: (inputElem, 1), \
    lambda intermediateElem, inputElem: \
        (intermediateElem[0]+inputElem, intermediateElem[1]+1),
    lambda intermediateElem1, intermediateElem2: \
        (intermediateElem1[0]+intermediateElem2[0], \
         intermediateElem1[1]+intermediateElem2[1])
)
```

CombineByKey transformation: Example

```
# Create the local python list
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]
```

Given an input value (an age) and an intermediate value (sum ages, num represented values), it combines them and returns a new updated tuple (sum ages, num represented values)

```
# the number of input pairs for each name (key)
sumNumPerNamePairRDD=nameAgePairRDD.combineByKey(\
    lambda inputElem: (inputElem, 1), \
```

```
lambda intermediateElem, inputElem: \
(intermediateElem[0]+inputElem, intermediateElem[1]+1),
```

```
lambda intermediateElem1, intermediateElem2: \
(intermediateElem1[0]+intermediateElem2[0], \
intermediateElem1[1]+intermediateElem2[1])
```

```
)
```

CombineByKey transformation: Example

```
# Create the local python list
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]
```

Given two intermediate result tuples (sum ages, num represented values), it combines them and returns a new updated tuple (sum ages, num represented values)

```
# the number of input pairs for each name (key)
sumNumPerNamePairRDD=nameAgePairRDD.combineByKey(\
    lambda inputElem: (inputElem, 1), \

    lambda intermediateElem, inputElem: \
        (intermediateElem[0]+inputElem, intermediateElem[1]+1),

    lambda intermediateElem1, intermediateElem2: \
        (intermediateElem1[0]+intermediateElem2[0], \
         intermediateElem1[1]+intermediateElem2[1])
)
```

CombineByKey transformation: Example

```
# Compute the average for each name
avgPerNamePairRDD = \
sumNumPerNamePairRDD.map(lambda pair: (pair[0], pair[1][0]/pair[1][1]))

# Store the result in an output folder
avgPerNamePairRDD.saveAsTextFile(outputPath)
```

CombineByKey transformation: Example

Compute the average for each name

```
avgPerNamePairRDD = \
sumNumPerNamePairRDD.map(lambda pair: (pair[0], pair[1][0]/pair[1][1]))
```

Store the result in an output folder

```
avgPerNamePairRDD.saveAsTextFile("output")
```

Compute the average age for each key (i.e., for each name) by combining "sum ages" and "num represented values".

Each input pair is characterized by a value that is a tuple containing (sum ages, num represented values).

GroupByKey transformation

GroupByKey transformation

- Goal
 - Create a new RDD of key-value pairs where there is **one pair for each distinct key k** of the input RDD of key-value pairs
 - The value associated with key k in the new RDD of key-value pairs is the list of values associated with k in the input RDD of key-value pairs
- Method
 - The groupByKey transformation is based on the **groupByKey()** method of the **RDD** class

GroupByKey transformation

- If you are grouping values per key to perform then an aggregation such as sum or average over the values of each key then groupByKey is not the right choice
 - **reduceByKey, aggregateByKey or combineByKey** provide **better performances for associative and commutative aggregations**
- **groupByKey** is useful if you need to **apply** an aggregation/compute **a function that is not associative**

GroupByKey transformation

- Shuffle
 - A **shuffle** operation is executed for computing the result of the **groupByKey()** transformation
 - Each group/key is associated with/is composed of values which are stored in different partitions of the input RDD

GroupByKey transformation: Example

- Create an RDD from a local python list containing the pairs
 - ("Paolo", 40)
 - ("Giorgio", 22)
 - ("Paolo", 35)
 - The key is the first name of a user and the value is his/her age
- Store the results in an output HDFS folder. The output contains one line for each name followed by the ages of all the users with that name

GroupByKey transformation: Example

```
# Create the local python list
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]

# Create the RDD of pairs from the local collection
nameAgePairRDD = sc.parallelize(nameAge)

# Create one group for each name with the list of associated ages
agesPerNamePairRDD = nameAgePairRDD.groupByKey()

# Store the result in an output folder
agesPerNamePairRDD.mapValues(lambda listValues: list(listValues))
                    .saveAsTextFile(outputPath);
```

GroupByKey transformation: Example

```
# Create the local python list
```

```
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]
```

```
# Create the RDD of pairs from the local collection
```

```
nameAgePairRDD = sc.parallelize(nameAge)
```

```
# Create one group for each name with the list of associated ages
```

```
agesPerNamePairRDD = nameAgePairRDD.groupByKey()
```

In this RDD of key-value pairs each tuple is composed of

- a string (key of the pair)

- a "collection" of integers (the value of the pair) – a ResultIterable object

GroupByKey transformation: Example

```
# Create the local python list  
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]
```

This part is used to format the content of the value part of each pair before storing the result in the output folder.

- This transforms a ResultIterable object to a Python list
- Without this "map" the output will contains the pointers to ResultIterable objects instead of a readable list of integer values

```
# Store the result in an output folder  
agesPerNamePairRDD.mapValues(lambda listValues: list(listValues))  
                    .saveAsTextFile(outputPath);
```

MapValues transformation

MapValues transformation

- Goal
 - Apply a function **f** over the value of each pair of an input RDD or key-value pairs and return a new RDD of key-value pairs
 - One pair is created in the returned RDD for each input pair
 - The key of the created pair is equal to the key of the input pair
 - The value of the created pair is obtained by applying the function **f** on the value of the input pair
 - The data type of the values of the new RDD of key-value pairs can be different from the data type of the values of the “input” RDD of key-value pairs
 - The data type of the key is the same

MapValues transformation

- Method
 - The mapValues transformation is based on the **mapValues(f)** method of the **RDD** class
 - A function **f** is passed to the mapValues method
 - **f** contains the code that is applied to transform each input value into the a new value that is stored in the RDD of key-value pairs
 - The returned RDD of pairs contains a number of key-value pairs equal to the number of key-value pairs of the input RDD of pairs
 - The key part is not changed

MapValues transformation: Example

- Create an RDD from a local python list containing the pairs
 - ("Paolo", 40)
 - ("Giorgio", 22)
 - ("Paolo", 35)
 - The key is the first name of a user and the value is his/her age
- Increase the age of each user (+1 year) and store the result in the HDFS file system
 - One output line per user

MapValues transformation: Example

```
# Create the local python list
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]

# Create the RDD of pairs from the local collection
nameAgePairRDD = sc.parallelize(nameAge)

# Increment age of all users
plusOnePairRDD = nameAgePairRDD.mapValues(lambda age: age+1)

# Save the result on disk
plusOnePairRDD.saveAsTextFile(outputPath)
```

FlatMapValues transformation

FlatMapValues transformation

- Goal
 - Apply a function **f** over the value of each pair of an input RDD or key-value pairs and return a new RDD of key-value pairs
 - **f** returns a list of values for each input value
 - A list of pairs is inserted in the returned RDD for each input pair
 - The key of the created pairs is equal to the key of the input pair
 - The values of the created pairs are obtained by applying the function **f** on the value of the input pair
 - The data type of the values of the new RDD of key-value pairs can be different from the data type of the values of the “input” RDD of key-value pairs
 - The data type of the key is the same

FlatMapValues transformation

- Method
 - The flatMapValues transformation is based on `flatMapValues(f)` method of the `RDD` class
 - A function `f` is passed to the `mapValues` method
 - `f` contains the code that is applied to transform each input value into a set of new values that are stored in the new RDD of key-value pairs
 - The keys of the input pairs are not changed

FlatMapValues transformation: Example

- Create an RDD from a local python list containing the pairs
 - ("Sentence#1", "Sentence test")
 - ("Sentence#2", "Sentence test number 2")
 - ("Sentence#3", "Sentence test number 3")
- Select the words of each sentence and store in the HDFS file system one pair (senteceld, word) per line

FlatMapValues transformation: Example

```
# Create the local python list
sentences = [("Sentence#1", "Sentence test"), \
             ("Sentence#2", "Sentence test number 2"), \
             ("Sentence#3", "Sentence test number 3")]

# Create the RDD of pairs from the local collection
sentPairRDD = sc.parallelize(sentences)

# "Extract" words from each sentence
sentIdWord = sentPairRDD.flatMapValues(lambda s: s.split(' '))

# Save the result on disk
sentIdWord.saveAsTextFile(outputPath)
```

Keys transformation

Keys transformation: Example

- Goal
 - Return the list of keys of the input RDD of pairs and store them in a new RDD
 - The returned RDD is not an RDD of key-value pairs
 - The returned RDD is a “standard” RDD of “single” elements
 - **Duplicates** keys **are not removed**
- Method
 - The keys transformation is based on the **keys()** method of the **RDD** class

Keys transformation: Example

- Create an RDD from a local python list containing the pairs
 - ("Paolo", 40)
 - ("Giorgio", 22)
 - ("Paolo", 35)
 - The key is the first name of a user and the value is his/her age
- Store the names of the input users in an output HDFS folder. The output contains one name per line (duplicate names are removed)

Keys transformation: Example

```
# Create the local python list
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]

# Create the RDD of pairs from the local collection
nameAgePairRDD = sc.parallelize(nameAge)

# Select the key part of the input RDD of key-value pairs
namesRDD = nameAgePairRDD.keys().distinct()

# Store the result in an output folder
namesRDD.saveAsTextFile(outputPath);
```

Values transformation

Values transformation

- Goal
 - Return the list of values of the input RDD of pairs and store them in a new RDD
 - The returned RDD is not an RDD of key-value pairs
 - The returned RDD is a “standard” RDD of “single” elements
 - **Duplicates** values **are not removed**
- Method
 - The values transformation is based on the **values()** method of the **RDD** class

Values transformation: Example

- Create an RDD from a local python list containing the pairs
 - ("Paolo", 40)
 - ("Giorgio", 22)
 - ("Paolo", 22)
 - The key is the first name of a user and the value is his/her age
- Store the ages of the input users in an output HDFS folder.
 - The output contains one age per line
 - Duplicate ages/values are not removed

Values transformation: Example

```
# Create the local python list
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 22)]

# Create the RDD of pairs from the local collection
nameAgePairRDD = sc.parallelize(nameAge)

# Select the value part of the input RDD of key-value pairs
agesRDD = nameAgePairRDD.values()

# Store the result in an output folder
agesRDD.saveAsTextFile(outputPath);
```

SortByKey transformation

SortByKey transformation

- Goal
 - Return a new RDD of key-value pairs obtained by sorting, in ascending order, the pairs of the input RDD by key
 - Note that the final order is related to the default sorting function of the data type of the input keys
 - The content of the new RDD of key-value pairs is the same of the input RDD but the pairs are sorted by key in the new returned RDD

SortByKey transformation

- Method
 - The sortByKey transformation is based on the `sortByKey()` method of the `RDD` class
 - Pairs are sorted by key in ascending order
 - The `sortByKey(ascending)` method of the `RDD` class is also available
 - This method allows specifying if the sort order is ascending or descending by means of a Boolean parameter
 - True = ascending
 - False = descending

SortByKey transformation

- Shuffle
 - A **shuffle** operation is executed for computing the result of the **sortByKey()** transformation
 - Pairs from different partitions of the input RDD must be compared to sort the input pairs by key

SortByKey transformation: Example

- Create an RDD from a local python list containing the pairs
 - ("Paolo", 40)
 - ("Giorgio", 22)
 - ("Paolo", 35)
 - The key is the first name of a user and the value is his/her age
- Sort the users by name and store the result in the HDFS file system

SortByKey transformation: Example

```
# Create the local python list
nameAge = [ ("Paolo", 40), ("Giorgio", 22), ("Paolo", 35)]

# Create the RDD of pairs from the local collection
nameAgePairRDD = sc.parallelize(nameAge)

# Sort by name the content of the input RDD of key-value pairs
sortedNameAgePairRDD = nameAgePairRDD.sortByKey()

# Store the result in an output folder
sortedNameAgePairRDD.saveAsTextFile(outputPath);
```

Transformations on RDDs of key-value pairs: Summary

Transformations on RDDs of key-value pairs: Summary

- All the examples reported in the following tables are applied on an RDD of pairs containing the following tuples (pairs)
 - [("k1", 2), ("k3", 4), ("k3", 6)]
 - The key of each tuple is a string
 - The value of each tuple is an integer

Transformations on RDDs of key-value pairs: Summary

Transformation	Purpose	Example of applied function	Result
reduceByKey(f)	<p>Return an RDD of pairs containing one pair for each key of the "input" RDD of pairs. The value of each pair of the new RDD of pairs is obtained by combining the values of the input RDD associated with the same key.</p> <p>The "input" RDD of pairs and the new RDD of pairs have the same data type.</p>	<p>reduceByKey(lambda v1, v2: v1+v2)</p> <p>Sum values per key</p>	<p>[("k1", 2), ("k3", 10)]</p>

Transformations on RDDs of key-value pairs: Summary

Transformation	Purpose	Example of applied function	Result
<code>foldByKey(zeroValue, op)</code>	Similar to the <code>reduceByKey()</code> transformation. However, <code>foldByKey()</code> is characterized also by a zero value	<code>foldByKey(0, lambda v1, v2: v1+v2)</code> Sum values per key. The zero value is 0	<code>[("k1", 2), ("k3", 10)]</code>

Transformations on RDDs of key-value pairs: Summary

Transformation	Purpose	Example of applied function	Result
<code>combineByKey(createCombiner, mergeValue, mergeCombiner)</code>	<p>Return an RDD of key-value pairs containing one pair for each key of the "input" RDD of pairs. The value of each pair of the new RDD is obtained by combining the values of the input RDD associated with the same key.</p> <p>The values of the "input" RDD of pairs and the values of the new (returned) RDD of pairs can be characterized by different data types.</p>	<pre>combineByKey(lambda e: (e, 1), \ lambda c, e: (c[0]+e, c[1]+1), \ lambda c1, c2: (c1[0]+c2[0], c1[1]+c2[1]))</pre> <p>Sum values by key and count the number of pairs by key in one single step</p>	<pre>[("k1", (2,1)), ("k3", (10,2))]</pre>

Transformations on RDDs of key-value pairs: Summary

Transformation	Purpose	Example of applied function	Result
groupByKey()	<p>Return an RDD of pairs containing one pair for each key of the "input" RDD of pairs.</p> <p>The value of each pair of the new RDD of pairs is a "collection" containing all the values of the input RDD associated with one of the input keys.</p>	groupByKey()	[("k1", [2]), ("k3", [4, 6])]

Transformations on RDDs of key-value pairs: Summary

Transformation	Purpose	Example of applied function	Result
mapValues(f)	<p>Apply a function over each pair of an RDD of pairs and return a new RDD of pairs. The applied function returns one pair for each pair of the "input" RDD of pairs. The function is applied only on the value part without changing the key. The values of the "input" RDD and the values of new RDD can have different data types.</p>	<p>mapValues(lambda v: v+1)</p> <p>Increment the value part by 1</p>	<p>[("k1", 3), ("k3", 5), ("k3", 7)]</p>

Transformations on RDDs of key-value pairs: Summary

Transformation	Purpose	Example of applied function	Result
<code>flatMapValues(f)</code>	<p>Apply a function over each pair of an RDD of pairs and return a new RDD of pairs. The applied function returns a set of pairs (from 0 to many) for each pair of the "input" RDD of pairs. The function is applied only on the value part without changing the key. The values of the "input" RDD and the values of new RDD can have different data types.</p>	<p><code>flatMapValues(lambda v: list(range(v,6)))</code></p> <p>for each input pair (k,v), the set of pairs (k,u) with values of u from v to 5 are returned and included in the new RDD</p>	<p><code>[("k1", 2), ("k1", 3), ("k1", 4), ("k1", 5), ("k3", 4), ("k3", 5)]</code></p>

Transformations on RDDs of key-value pairs: Summary

Transformation	Purpose	Example of applied function	Result
keys()	Return an RDD containing the keys of the input pairRDD	keys()	["k1", "k3", "k3"]
values()	Return an RDD containing the values of the input pairRDD	values()	[2, 4, 6]
sortByKey()	Return a PairRDD sorted by key. The "input" PairRDD and the new PairRDD have the same data type.	sortByKey() -	[("k1", 2), ("k3", 4), ("k3", 6)]

RDD-based programming

Transformations on two RDDs of key-value pairs

Transformations on two RDDs of pairs

- Spark supports also some transformations that are applied on two RDDs of key-value pairs at the same time
 - `subtractByKey`, `join`, `coGroup`, etc.

SubtractByKey transformation

SubtractByKey transformation

- Goal
 - Create a new RDD of key-value pairs containing only the pairs of the first input RDD of pairs associated with a key that is not appearing as key in the pairs of the second input RDD or pairs
 - The data type of the new RDD of pairs is the same of the “first input” RDD of pairs
 - The two input RDD of pairs must have the same type of keys
 - The data type of the values can be different

SubtractByKey transformation

- Method
 - The subtractByKey transformation is based on the `subtractByKey(other)` method of the `RDD` class
 - The two input RDDs of pairs analyzed by `subtractByKey` are the one on which the method is invoked and the one passed as parameter (i.e., `other`)

SubtractByKey transformation

- Shuffle
 - A **shuffle** operation is executed for computing the result of the **subtractByKey()** transformation
 - Keys from different partitions of the two input RDDs must be compared

SubtractByKey transformation: Example

- Create two RDDs of key-value pairs from two local python lists
 - First list – Profiles of the users of a blog (username, age)
 - [("PaoloG", 40), ("Giorgio", 22), ("PaoloB", 35)]
 - Second list – Banned users (username, motivation)
 - [("PaoloB", "spam"), ("Giorgio", "Vandalism")]
- Create a new RDD of pairs containing only the profiles of the non-banned users

SubtractByKey transformation: Example

```
# Create the first local python list
profiles = [ ("PaoloG", 40), ("Giorgio", 22), ("PaoloB", 35)]

# Create the RDD of pairs from the profiles local list
profilesPairRDD = sc.parallelize (profiles)

# Create the second local python list
banned = [ ("PaoloB", "spam"), ("Giorgio", "Vandalism")]

# Create the RDD of pairs from the banned local list
bannedPairRDD = sc.parallelize (banned)

# Select the profiles of the "good" users
selectedProfiles = profilesPairRDD.subtractByKey(bannedPairRDD)
```

Join transformation

Join transformation

- Goal
 - Join the key-value pairs of two RDDs of key-value pairs based on the value of the key of the pairs
 - Each pair of the input RDD of pairs is combined with all the pairs of the other RDD of pairs with the same key
 - The new RDD of key-value pairs
 - Has the same key data type of the “input” RDDs of pairs
 - Has a tuple as value (the pair of values of the two joined input pairs)
 - The two input RDDs of key-value pairs
 - Must have the same type of keys
 - But the data types of the values can be different

Join transformation

- Method
 - The join transformation is based on the `join(other)` method of the `RDD` class
 - The two input RDDs of pairs analyzed by join are the one on which the method is invoked and the one passed as parameter (i.e., `other`)

Join transformation

- Shuffle
 - A **shuffle** operation is executed for computing the result of the **join()** transformation
 - Keys from different partitions of the two input RDDs must be compared and values from different partitions must be retrieved

Join transformation: Example

- Create two RDDs of key-value pairs from two local python lists
 - First list – List of questions (QuestionId, Text of the question)
 - [(1, "What is .. ?"), (2, "Who is ..?")]
 - Second list – List of answers (QuestionId, Text of the answer)
 - [(1, "It is a car"), (1, "It is a byke"), (2, "She is Jenny")]
- Create a new RDD of pairs to associate each question with its answers
 - One pair for each possible pair question - answer

Join transformation: Example

```
# Create the first local Python list
questions= [(1, "What is .. ?"), (2, "Who is ..?")]

# Create the RDD of pairs from the local list
questionsPairRDD = sc.parallelize(questions)

# Create the second local python list
answers = [(1, "It is a car"), (1, "It is a byke"), (2, "She is Jenny")]

# Create the RDD of pairs from the local list
answersPairRDD = sc.parallelize(answers)

# Join questions with answers
joinPairRDD = questionsPairRDD.join(answersPairRDD)
```

Join transformation: Example

```
# Create the first local Python list
questions= [(1, "What is ..?"), (2, "Who is ..?")]
```

```
# Create the RDD of pairs from the local list
questionsPairRDD = sc.parallelize (questions)
```

The key part of the returned RDD of pairs is an integer number

The value part of the returned RDD of pairs is tuple containing two values: (question, answer)

```
# Join questions with answers
```

```
joinPairRDD = questionsPairRDD.join(answersPairRDD)
```

CoGroup transformation

Cogroup transformation

- Goal
 - Associated each key **k** of the two input RDDs of key-value pairs with
 - The list of values associated with **k** in the first input RDD of pairs
 - And the list of values associated with **k** in the second input RDD of pairs
 - The new RDD of key-value pairs
 - Has the same key data type of the two “input” RDDs of pairs
 - Has a tuple as value (the two lists of values of the two input RDDs of pairs)
 - The two input RDDs of key-value pairs
 - Must have the same type of keys
 - But the data types of the values can be different

Cogroup transformation

- Method
 - The cogroup transformation is based on the `cogroup(other)` method of the `RDD` class
 - The two input RDDs of pairs analyzed by cogroup are the one on which the method is invoked and the one passed as parameter (i.e., `other`)

Cogroup transformation

- Shuffle
 - A **shuffle** operation is executed for computing the result of the **cogroup()** transformation
 - Keys from different partitions of the two input RDDs must be compared and values from different partitions must be retrieved

Cogroup transformation: Example

- Create two RDDs of key-value pairs from two local python lists
 - First list – List of liked movies (userId, likedMovies)
 - [(1, "Star Trek"), (1, "Forrest Gump"), (2, "Forrest Gump")]
 - Second list – List of liked directors (userId, likedDirector)
 - [(1, "Woody Allen"), (2, "Quentin Tarantino"), (2, "Alfred Hitchcock")]

Cogroup transformation: Example

- Create a new RDD of pairs containing one pair for each userId (key) associated with
 - The list of liked movies
 - The list of liked directors

Cogroup transformation: Example

- Inputs
 - [(1, "Star Trek"), (1, "Forrest Gump"), (2, "Forrest Gump")]
 - [(1, "Woody Allen"), (2, "Quentin Tarantino"), (2, "Alfred Hitchcock")]
- Output
 - (1, (["Star Trek", "Forrest Gump"], ["Woody Allen"]))
 - (2, (["Forrest Gump"], ["Quentin Tarantino", "Alfred Hitchcock"]))

Cogroup transformation: Example

```
# Create the first local python list
movies= [(1, "Star Trek"), (1, "Forrest Gump"), (2, "Forrest Gump")]
```

```
# Create the RDD of pairs from the first local list
moviesPairRDD = sc.parallelize(movies)
```

```
# Create the second local python list
directors = [ (1, "Woody Allen"), (2, "Quentin Tarantino"), \
              (2, "Alfred Hitchcock")]
```

```
# Create the RDD of pairs from the second local list
directorsPairRDD = sc.parallelize(directors)
```

```
# Cogroup movies and directors per user
cogroupPairRDD = moviesPairRDD.cogroup(directorsPairRDD)
```

Cogroup transformation: Example

```
# Create the first local python list
movies= [(1, "Star Trek"), (1, "Forrest Gump"), (2, "Forrest Gump")]
```

```
# Create the RDD of pairs from the first local list
moviesPairRDD = sc.parallelize(movies)
```

```
# Create the second local python list
directors = [ (1, "Woody Allen"), (2, "Quentin Tarantino"), \
              (2, "Alfred Hitchcock")]
```

Note that the value part of the returned tuples is a tuple containing two "lists":

- The first value contains the "list" of movies (iterable) liked by a user
- The second value contains the "list" of directors (iterable) liked by a user

```
# Cogroup movies and directors per user
cogroupPairRDD = moviesPairRDD.cogroup(directorsPairRDD)
```

Transformations on two RDDs of key-value pairs: Summary

Transformations on two RDDs of key-value pairs: Summary

- All the examples reported in the following tables are applied on the following two RDDs of key-value pairs
 - inputRDD1: [('k1', 2), ('k3', 4), ('k3', 6)]
 - inputRDD2: [('k3', 9)]

Transformations on two RDDs of key-value pairs: Summary

Transformation	Purpose	Example	Result
<code>subtractByKey(other)</code>	Return a new RDD of key-value pairs. The returned pairs are those of input RDD on which the method is invoked such that the key part does not occur in the keys of the RDD that is passed as parameter. The values are not considered to take the decision.	<code>inputRDD1.subtractByKey(inputRDD2)</code>	<code>[('k1',2)]</code>
<code>join(other)</code>	Return a new RDD of pairs corresponding to join of the two input RDDs. The join is based on the value of the key.	<code>inputRDD1.join(inputRDD2)</code>	<code>[('k3', (4,9)), ('k3', (6,9))]</code>

Transformations on two RDDs of key-value pairs: Summary

Transformation	Purpose	Example	Result
cogroup(other)	<p>For each key k in one of the two input RDDs of pairs, return a pair (k, tuple), where tuple contains:</p> <ul style="list-style-type: none">- the list (iterable) of values of the first input RDD associated with key k- the list (iterable) of values of the second input RDD associated with key k	<pre>inputRDD1. cogroup (inputRDD2)</pre>	<pre>[('k1', ([2], [])) , ('k3', ([4, 6], [9]))]</pre>

Actions on RDDs of key-value pairs

Actions on RDDs of key-value pairs

- Spark supports also some specific actions on RDDs of key-value pairs
 - `countByKey`, `collectAsMap`, `lookup`

CountByKey action

CountByKey action

- Goal
 - The countByKey action returns a local python dictionary containing the information about the number of elements associated with each key in the input RDD of key-value pairs
 - i.e., the number of times each key occurs in the input RDD
 - **Pay attention to the number of distinct keys of the input RDD of pairs**
 - **If the number of distinct keys is large, the result of the action cannot be stored in a local variable of the Driver**

CountByKey action

- Method
 - The countByKey action is based on the `countByKey()` method of the `RDD` class
- **Data are sent on the network** to compute the final result

CountByKey action: Example 1

- Create an RDD of pairs from the following python list
 - [("Forrest Gump", 4), ("Star Trek", 5), ("Forrest Gump", 3)]
 - Each pair contains a movie and the rating given by someone to that movie
- Compute the number of ratings for each movie

CountByKey action: Example 1

```
# Create the local python list
movieRating= [("Forrest Gump", 4), ("Star Trek", 5), ("Forrest Gump", 3)]

# Create the RDD of pairs from the local collection
movieRatingRDD = sc.parallelize(movieRating)

# Compute the number of rating for each movie
movieNumRatings = movieRatingRDD.countByKey()

# Print the result on the standard output
print(movieNumRatings)
```

CountByKey action: Example 1

```
# Create the local python list
```

```
movieRating= [("Forrest Gump", 4), ("Star Trek", 5), ("Forrest Gump", 3)]
```

```
# Create the RDD of pairs from the local collection
```

```
movieRatingRDD = sc.parallelize(movieRating)
```

```
# Compute the number of rating for each movie
```

```
movieNumRatings = movieRatingRDD.countByKey()
```

Pay attention to the size of the returned local python dictionary (i.e., the number of distinct movies in this case).

CollectAsMap action

CollectAsMap action

- Goal
 - The collectAsMap action returns a local dictionary containing the same pairs of the considered input RDD of pairs
 - **Pay attention to the size of the returned RDD**
 - **Data are sent on the network**
- Method
 - The collectAsMap action is based on the **collectAsMap()** method of the **RDD** class

CollectAsMap action

- **Pay attention** that the **collectAsMap** action **returns a dictionary** object
- **A dictionary cannot contain duplicate keys**
 - Each key can be associated with at most one value
 - If the “input” RDD of pairs contains more than one pair with the same key, only one of those pairs is stored in the returned local python dictionary
 - Usually, the last one occurring in the input RDD of pairs
- Use `collectAsMap` only if you are sure that each key appears only once in the input RDD of key-value pairs

CollectAsMap vs collect

- The collectAsMap() action returns a local dictionary while collect() return a list of key-value pairs (i.e., a list of tuples)
 - The list of pairs returned by collect() can contain more than one pair associated with the same key

CollectAsMap action: Example 1

- Create an RDD of pairs from the following python list
 - [("User1", "Paolo"), ("User2", "Luca"), ("User3", "Daniele")]
 - Each pair contains a userId and the name of the user
- Retrieve the pairs of the created RDD of pairs and store them in a local python dictionary that is instantiated in the Driver

CollectAsMap action: Example 1

```
# Create the local python list
users = [("User1", "Paolo"), ("User2", "Luca"), ("User3", "Daniele")]

# Create the RDD of pairs from the local list
usersRDD = sc.parallelize(users)

# Retrieve the content of usersRDD and store it in a
# local python dictionary
retrievedPairs = usersRDD.collectAsMap()

# Print the result on the standard output
print(retrievedPairs)
```

CollectAsMap action: Example 1

```
# Create the local python list
users = [("User1", "Paolo"), ("User2", "Luca"), ("User3", "Daniele")]

# Create the RDD of pairs from the local list
usersRDD = sc.parallelize(users)

# Retrieve the content of usersRDD and store it in a
# local python dictionary
retrievedPairs = usersRDD.collectAsMap()
```

Pay attention to the size of the returned local python dictionary (i.e., the number of distinct users in this case).

Lookup action

Lookup action

- Goal
 - The lookup(**k**) action returns a local python list containing the values of the pairs of the input RDD associated with the key **k** specified as parameter
- Method
 - The lookup action is based on the **lookup(key)** method of the **RDD** class

Lookup action: Example 1

- Create an RDD of pairs from the following python list
 - [("Forrest Gump", 4), ("Star Trek", 5), ("Forrest Gump", 3)]
 - Each pair contains a movie and the rating given by someone to that movie
- Retrieve the ratings associated with the movie "Forrest Gump" and store them in a local python list in the Driver

Lookup action: Example 1

```
# Create the local python list
movieRating= [("Forrest Gump", 4), ("Star Trek", 5), ("Forrest Gump", 3)]

# Create the RDD of pairs from the local collection
movieRatingRDD = sc.parallelize(movieRating)

# Select the ratings associated with "Forrest Gump"
movieRatings = movieRatingRDD.lookup("Forrest Gump")

# Print the result on the standard output
print(movieRatings)
```

Lookup action: Example 1

```
# Create the local python list
```

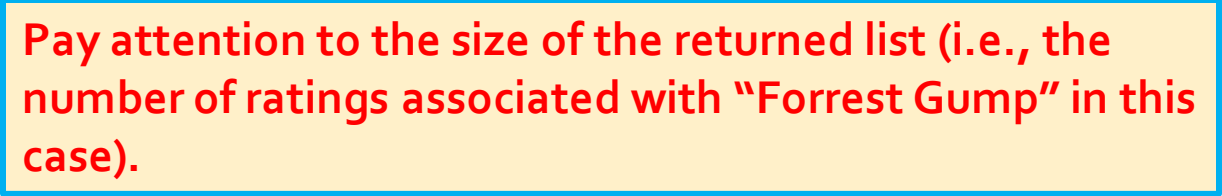

```
movieRating= [("Forrest Gump", 4), ("Star Trek", 5), ("Forrest Gump", 3)]
```

```
# Create the RDD of pairs from the local collection
```

```
movieRatingRDD = sc.parallelize(movieRating)
```

```
# Select the ratings associated with "Forrest Gump"
```

```
movieRatings = movieRatingRDD.lookup("Forrest Gump")
```

Pay attention to the size of the returned list (i.e., the number of ratings associated with "Forrest Gump" in this case).

Actions on RDDs of key-value pairs: Summary

Actions on RDDs of key-value pairs:

Summary

- All the examples reported in the following tables are applied on the following RDD of key-value pairs
 - inputRDD: [('k1', 2), ('k3', 4), ('k3', 6)]

Actions on RDDs of key-value pairs:

Summary

Transformation	Purpose	Example	Result
<code>countByKey()</code>	Return a local python dictionary containing the number of elements in the input RDD for each key of the input RDD of pairs	<code>inputRDD.countByKey()</code>	<code>{('k1',1), ('k3',2)}</code>
<code>collectAsMap()</code>	Return a local python dictionary containing the pairs of the input RDD of pairs	<code>inputRDD.collectAsMap()</code>	<code>{('k1', 2), ('k3', 6)}</code> Or <code>{('k1', 2), ('k3', 4)}</code> Depending on the order of the pairs in the input RDD of pairs
<code>lookup(key)</code>	Return a local python list containing all the values associated with the key specified as parameter	<code>inputRDD.lookup('k3')</code>	<code>[4, 6]</code>
